**Abstract.** Previous versions of Trust is Risk present the Conservative and the Idle strategy as distinct and unrelated. This work is an attempt to generalize this idea into a continuous spectrum of strategies, the two ends of which correspond to the two previously defined strategies. Prior to querying the system for an indirect trust towards Bob, Alice can attribute a specific expected strategy to each one of the participating players, or even fine-tune the response of each player to a steal action from each one of the players she directly trusts. The system then executes the generalized MaxFlow [1] to determine the indirect trust from Alice to Bob, given the specified strategies of the rest of the players.

The generalized MaxFlow algorithm expects as input a graph with capacities as well as a *gain factor* for each edge, which in our case will be a number in  $[0, 1]$ . Intuitively, the gain factor of an edge  $(v, w)$  represents the ratio of "leakage" this edge causes. In our case, it represents the percentage of funds that  $v$  will try to replenish when  $w$  steals from her. For the sake of example, consider the following graph:

A gain factor of 0 means that  $v$  will tolerate any amount of stolen funds by  $w$  without trying to replenish them by stealing others that directly trust her, whereas a gain factor of 1 means that  $v$  will try to replenish any amount of stolen funds by  $w$ . If the gain factor is 0 on edges  $(v, w)$  for all  $w \in \mathcal{V}$ , then  $v$  is following the Idle strategy, whereas if the gain factor is 1 on edges  $(v, w)$  for all  $w \in \mathcal{V}$ , then  $v$  is following the Conservative strategy.
